# Potential for Hydrocyanic Acid Poisoning of Livestock by Indiangrass

K.P. VOGEL, F.A. HASKINS, AND H.J. GORZ

## Abstract

Hydrocyanic acid or prussic acid poisoning of livestock by sorghums [*Sorghum bicolor* (L.) Moench] and sudangrasses [*Sorghum sudanense* (Piper) Stapf] is caused by the digestive liberation of hydrocyanic acid (HCN) from the cyanogenic compound, dhurrin [(*S*)-*p*-hydroxymandelonitrile  $\beta$ -D-glucopyranoside] found in tissue of these plants. Recent research documented that dhurrin is also present in indiangrass [*Sorghastrum nutans* (L.) Nash] seedlings. The purpose of this study was to determine the hydrocyanic acid potential (HCN-p) of forage from established stands of indiangrass. Five cultivars representative of indiangrass germplasm of the Great Plains were sampled during the growing season for 2 years from 2 sites in eastern Nebraska. The HCN-p of the indiangrass sampled in this study exceeded 750 mg<sup>-1</sup> kg dry wt. (dangerous level) only in spring when new growth was 20 cm tall or less. Levels were less than 500 mg<sup>-1</sup> kg (safe) when new growth was at least 40 cm tall and were very low (<200 mg<sup>-1</sup> kg) or not detected when the forage was over 1 m tall. Pure stands of indiangrass that are grazed when the new growth is less than 20 cm tall could be lethal to livestock.

**Key Words:** prussic acid, HCN, dhurrin, poisonous plants, *Sorghastrum nutans*

Dhurrin [(*S*)-*p*-hydroxymandelonitrile  $\beta$ -D-glucopyranoside] was the first cyanogenic compound isolated from a *Gramineae* (Tjon Sie Fat 1977). It was isolated from sorghum [*Sorghum bicolor* (L.) Moench] plants in 1902 by Dunstan and Henry (1902). When hydrolyzed, dhurrin yields hydrocyanic acid (HCN), glucose, and *p*-hydroxybenzaldehyde (*p*-HB) in equimolar amounts. In young sorghum leaves, dhurrin is localized in vacuoles of epidermal cells while the enzymes responsible for the release of HCN from dhurrin are located in mesophyll cells (Kojima et al. 1979). This separation of enzyme and substrate probably accounts for the fact that in healthy, intact leaf tissue little, if any, free cyanide is present.

In ruminants, mastication and subsequent rumen digestion of sorghum and sudangrass [*Sorghum sudanense* (Piper) Stapf] result in release of HCN. The released HCN is absorbed directly into the bloodstream from the rumen (Kingsbury 1964). The absorbed HCN inhibits cytochrome oxidase of the mitochondrial respiratory system thus causing asphyxiation at the cellular level (Kingsbury 1964, Solomonsen 1981). Ingestion of a lethal dose can result in death within 15 minutes to a few hours (Kingsbury 1964). Boyd et al. (1938) listed the following relative toxicities of sorghum and sudangrass forage at various HCN-p (hydrocyanic acid potential) levels (dry matter basis): 0 to 500 mg kg<sup>-1</sup> was considered safe to utilize; 500 to 750 mg kg<sup>-1</sup> was of doubtful toxicity; and above 750 mg kg<sup>-1</sup> was dangerous to utilize as feed. Dhurrin concentration of sorghum leaves is highest at the seedling stage and decreases as the plant matures. Dhurrin is also present in high concentrations in herbage regrowth after harvest.

The presence of dhurrin in other grasses was not firmly established until Gorz et al. (1979) reported it in seedlings of indiangrass [*Sorghastrum nutans* (L.) Nash]. Subsequently, Haskins et al. (1979) screened 39 grass species representing 14 genera and 2 tribes (*Andropogoneae* and *Tripsaceae*) and found dhurrin only in seedlings of *Sorghastrum nutans* and *Sorghastrum pellitum*. A spectrophotometric assay for HCN-p (Gorz et al. 1977) was used in these studies. This assay measured *p*-HB on the basis of its absorbance at 330nm. Since dhurrin degradation yields HCN and *p*-HB in equimolar amounts, HCN-p values can be calculated from *p*-HB concentrations. Results of Haskins et al. (1979) indicated that the HCN-p of indiangrass seedling tissue exceeded the levels considered to be safe in sorghums and could be as high as 3,000 mg<sup>-1</sup> kg on a dry weight basis. Haskins et al. (1979) also sampled tillers of established indiangrass plants for HCN-p. Their preliminary results indicated that the tiller leaves did contain dhurrin, but it was apparent that interfering substances in the mature plant tissue were confounding the assay. The seedling assay has subsequently been modified for use on mature plant tissue (Haskins et al. 1984).

The purpose of this study was to determine the HCN-p of forage from established stands of indiangrass by using the spectrophoto-

metric assay for mature tissue.

### Materials and Methods

Forage of 5 indiangrass cultivars representative of the germplasm of the Great Plains was sampled during 2 years at 2 eastern Nebraska sites. The cultivars and their origin (Hanson 1972) were: 'Holt' (northeast Nebraska), 'Nebraska 54' (southeast Nebraska), 'Oto' (southeast Nebraska and northeast Kansas), 'Osage' (east and central Kansas and Oklahoma), and 'Llano' (eastern New Mexico). Sites were the University of Nebraska Agricultural Research and Development Center at Mead, Neb. (35 km west of Omaha, Neb.) and the Leonard Christian farm in Pawnee County, NE (120 km south of Omaha). The soil at Mead was a Sharpsburg silty clay loam (Typic Argiudoll) while the Pawnee County soil was a Pawnee clay loam (Aquic Argiudoll). Replicated variety trials which included the cultivars listed above and some experimental strains were seeded at Mead in 1980 and at the Pawnee site in 1981. The experimental design was a randomized complete block with 6 replicates. Plots were  $4.3 \times 1.2$  m.

Forage aftermath from the previous growing season was removed by either mowing or burning prior to spring growth. The herbicides atrazine [6-chloro-N-ethyl-N'-(1-methylethyl)-1,3,5-triazine-2,4-diamine], alachlor [2-chloro-N-(2,6-diethylphenyl)-N-(methoxy-methyl)acetamide], and 2,4-D [(2,4-dichlorophenoxy)acetic acid] were used alone or in combination for weed control. Herbicides and nitrogen fertilizer ( $\text{NH}_4\text{NO}_3$ ) were applied in either April or early May before the indiangrasses had initiated spring growth. Nitrogen and herbicide rates, given in  $\text{kg ha}^{-1}$  for each location-year, were: (1) Mead in 1983—N, 112; atrazine, 1.1; alachlor, 2.2. (2) Mead in 1984—N, 112; alachlor, 2.2; 2,4-D, 1.1. (3) Pawnee in 1983—N, 56; atrazine, 2.2; alachlor, 1.1. (4) Pawnee in 1984—N, 74; atrazine, 3.3.

Three of the 6 replicates at each site were sampled for HCN-p in

1983 and 1984 at 3 different times during the growing season. In 1983, plots at Mead were sampled on 2 June, 26 June, and 12 Aug., while in 1984 they were sampled on 25 June, 13 July, and 6 Aug. In both years the Pawnee plots were sampled either the day before or the day after the Mead plots. All harvests except for the first harvest in 1983 were made with a sickle bar mower at a cutting height of 5 cm. A 0.6-m wide swath was cut across the width of a plot. The forage was collected and subsampled to obtain a 250- to 300-g sample for analyses. An equivalent area was harvested with hand clippers for the first harvest in 1983. Subsequent harvests were from areas of the plots that had not been harvested previously. Yields were not determined. Plant height (maximum natural height of leaves or stems) at the sampling date was measured. Harvested samples were dried in a  $70^\circ\text{C}$  oven for 48 hours, and the dry forage was immediately ground to pass a 1-mm screen. Subsamples of ground tissue were held in a freezer at about  $-17^\circ\text{C}$  until they were analyzed for HCN-p.

The HCN-p of the ground samples was determined by the spectrophotometric procedure described by Haskins et al. (1984) for mature sorghum leaves. In brief, portions of the dried, ground samples were autoclaved in water, a treatment which extracts dhurrin and breaks it down into its constituent parts, HCN, glucose, and *p*-HB. The *p*-HB was then extracted with ether, diluted in 0.1 M NaOH, and measured spectrophotometrically at 330 nm. Calculations of HCN-p were on a dry weight basis. Samples also were analyzed for in vitro dry matter digestibility (IVDMD) (Tilley and Terry 1963) and crude protein [Kjeldahl N  $\times 6.25$  (A.O.A.C. 1960)] to provide estimates of forage quality at the various sampling dates.

Analyses of variance procedures were used to analyze the data for a single harvest at a location and over locations for the same harvest.

## Results and Discussion

In eastern Nebraska, indiangrass begins growth in late April to early May, and grazing of warm-season pastures or range containing indiangrass is normally initiated in mid- to late-June. The initial 1983 harvest was about 2 weeks prior to the start of the grazing season. The second harvest in 1983 and the first harvest in 1984 were approximately at the time grazing normally begins. The third harvest for both years occurred at the time when high quality warm-season hay should be harvested from ungrazed pastures. The second harvest in 1984 represented an intermediate stage of maturity.

Mean values for HCN-p, plant height, IVDMD, and protein for the samples collected in 1983 and 1984 are listed in Tables 1 and 2, respectively. Based on the toxicity ranges reported by Boyd et al. (1938) and listed above in the introduction, 1983 first-harvest forage from some of the cultivars at both Mead and Pawnee was potentially dangerous ( $>750 \text{ mg kg}^{-1}$ ), but forage from the other 2 harvests in 1983 and from all three 1984 harvests was safe. During the 2-year period of the experiment, there were significant differences in HCN-p among cultivars for 6 of the 12 harvest-location combinations, but these differences were not consistent over locations or harvests. The primary factor affecting HCN-p of indiangrass herbage appears to be the stage of development of the plant with genotype or cultivar and environment having modifying effects. The cultivars used in this study represent materials initially collected from a broad array of sites in the Great Plains. It is reasonable to assume that similar HCN-p levels could be found in most indiangrass plants at similar stages of development.

Plant height has been used as a simple indicator of the stage at which sudangrasses and sorghum-sudangrass hybrids are safe to graze. Normally these summer annuals are safe to graze when the forage is at least 45 cm tall (Anderson and Guyer 1986). Our data indicate that plant height can also be used as an indicator of

HCN-p in indiangrass. In pastures containing only indiangrass, HCN poisoning of livestock could occur in late spring and early summer if indiangrass is grazed when plants are less than 20 cm tall. Our data indicate, however, that pure stands of indiangrass are safe to graze when the grass is 40 cm tall. Indiangrass in mixed stands in seeded pastures or in native rangelands would be diluted in the diet by other grasses and forbs, and the potential for HCN poisoning of livestock is thereby reduced. This type of dilution may account for the lack of reports of livestock death due to grazing indiangrass. Indiangrass is normally harvested for hay when it is 1 m or more in height; consequently, the possibility of HCN poisoning from indiangrass hay is remote. In forage sorghums and sudangrasses, stresses such as drought can result in elevated HCN-p levels (Harrington 1966). Under these conditions, increased HCN-p of indiangrass forage would also be expected.

The protein and IVDMD of indiangrass, like HCN-p, decreased as plants matured. Although there were differences among cultivars and locations for some of the harvests, these differences were not consistent. The protein content of the indiangrass forage that had potentially toxic levels of HCN-p was 18% or higher. Values of IVDMD exceeding 60% were obtained for forages that differed greatly in HCN-p. Available data do not support the use of either protein content or IVDMD as indicators of HCN-p. The spectrophotometric assay for HCN-p is relatively fast and simple, and it can be done with standard laboratory equipment (analytical balance, autoclave, spectrophotometer). If there is any doubt about the toxicity of indiangrass forage, the forage should be analyzed for HCN-p.

# Factors Affecting Dietary Preferences for Genotypes of a Hybrid Wheatgrass

DOREEN R. TRUSCOTT AND PAT O. CURRIE

## Abstract

Interspecific hybridization of grasses represents a valuable plant breeding procedure for developing new species with superior grazing value for livestock. Evaluations were made of the hybrid cross between quackgrass (*Elytrigia repens* [L.] Beauv.) × bluebunch wheatgrass (*Pseudoroegneria spicata* [Pursh.] Scribn and Smith) to determine how animal preferences for these hybrids were influenced by grazing season and year. Significant differences in the preference shown by steers as measured by bite counts in 1981 and percent utilization ( $P < 0.01$ ) in 1982 existed among the 46 clonal lines for each of the 2 successive years. Preference rankings for lines selected the first year were not identical to those selected a second year although lines with high preference rankings the first year were generally preferred the second year. A clonal line, designated line 30, was most preferred in 7 of 8 subtrials in 1981 and ranked in the top 3 preferred plants in all trials in 1982. There was a 4-week period in early summer when preference differences were minimal. It was attributed to the abundant regrowth on all lines at this time and was found to have a significant ( $P < 0.01$ ) effect on steers' dietary choices.

**Key Words:** bluebunch wheatgrass, quackgrass, forage, beef cattle

Interspecific hybridization of grasses represents a valuable plant breeding procedure to develop new species with superior grazing value for livestock. Particular success has been achieved by cross-

ing bluebunch wheatgrass (*Pseudoroegneria spicata* [Pursh.] Scribn and Smith) and quackgrass (*Elytrigia repens* [L.] Beauv.)<sup>1</sup> which was designated RS-1 and RS-2 (Asay and Dewey 1981). An obstacle to the release of this RS hybrid for commercial use, however, has been the screening of lines within the hybrid to determine their value to livestock as range forages. Preferences exhibited by livestock for these genotypes are of particular interest as they affect the extent to which the plants will be utilized.

Preliminary studies using bite count data were conducted by Currie et al. (1981) on a group of RS hybrid lines to evaluate relative preferences by beef cattle. It was concluded that cattle preferentially selected between and within certain hybrid lines. There did not appear to be a distinct relationship between animal preference and the selection criteria established by plant breeders. Results suggested that characteristics which plant breeders have traditionally used to select new plants may not be reliable indicators of animal preferences. Similar conclusions were made from trials conducted a second year by the same scientists.

Asay et al. (1968) found that relative dietary preference ratings by rabbits and sheep for some lines of reed canarygrass (*Phalaris arundinacea* [L.]) were consistently high and others consistently low. Genetically, it was found that factors which controlled relative palatabilities were transmitted to successive plant progeny. Barnes et al. (1970) reported a fairly high heritability for palatability in studies with reed canarygrass. Consistent differences in apparent palatability have also been reported among genotypes of other species (Peterson et al. 1958). Thus, the reality of breeding heritable characteristics into plants to develop grass cultivars which are more preferable to the grazing animal appears to be an attainable goal. However, evaluation of plant materials would be enhanced by a more thorough understanding of the diet selection process.

Authors are research associate, MAES, and range scientist, USDA-ARS, at the Fort Keogh Livestock and Range Research Station, Route 1, Box 2021, Miles City, Mont. 59301.

This research is a contribution from the USDA, Agricultural Research Service (USDA-ARS), Fort Keogh Livestock and Range Research Station and the Montana Agricultural Experiment Station (MAES). Contribution No. J-1841 from Montana Agr. Exp. Sta.

The research reported was also in partial fulfillment of a graduate degree by D.R. Truscott at Colorado State University, Fort Collins. The authors wish to gratefully acknowledge Drs. W.A. Laycock, K.H. Asay, G.V. Richardson, and B.W. Knapp, USDA-ARS, and Drs. C.D. Bonham, N.A. Daugherty, and E.T. Bartlett, CSU for their support and contributions.

Manuscript accepted 14 July 1987.

<sup>1</sup>Nomenclature follows that proposed by Dr. D.R. Dewey (1984), Crops Research Laboratory, Logan, Utah. Previous nomenclature was *Agropyron spicatum* for bluebunch wheatgrass and *Agropyron repens* for quackgrass.
